

Validating Wordscores: The Promises and
Pitfalls of Computational Text Scaling

-

Supplementary Material

Version 1.0

Appendix A: *Wordscores* estimation and assumptions

The estimation process begins with the researcher defining a set of reference texts that have positions on a dimension that we can assume with some confidence (for example, when they are obtained by an expert survey). Reference texts therefore need to be informative with regards to their content (words), and need to have a known position on the dimension of interest. *Wordscores*, implemented as a user-written package in Stata and R, begins by counting the frequency of words in each reference text and assigns a score to each of these words. To do so, *Wordscores* calculates the probability P that a word w appears in reference text r as follows:

$$P_{wr} = \frac{F_{wr}}{\sum_r F_{wr}} \quad (1)$$

where F_{wr} is the frequency of word w in reference text r . Using these probabilities, *Wordscores* calculates a score for each word w on each dimension of interest d as follows:

$$S_{wd} = \sum_r P_{wr} A_{rd} \quad (2)$$

where A_{rd} is the known position of reference text r on dimension d . To score each virgin text v on dimension d , *Wordscores* use the word scores S_{wd} obtained from reference texts as follows:

$$S_{vd} = \sum_w F_{wv} S_{wd} \quad (3)$$

According to Laver, Benoit & Garry (2003, 316), F_{wv} in equation 3 denotes ‘the relative frequency of each virgin text word [w], as a proportion of the *total number of words in the virgin text* [v]’ (emphasis added). However, all the statistical packages that have been written to implement *Wordscores*,¹ use a different definition of F_{wv} . Here the relative frequency of each virgin text word w is taken as a proportion of the total number of words *co-occurring between the reference and the virgin texts*. This inconsistency between the Laver et al. article and the software implementations is of no particular concern to how *Wordscores* work, but it does challenge the proof-of-concept

validation presented in the Laver et al. article as we will see in the following section.

Nevertheless, irrespective of how one defines F_{vv} , the S_{vd} scores only indicate the relative position of virgin texts to each other on dimension d . To be able to compare the scores of virgin texts to the scores of reference texts, we need one more step. *Wordscores* will transform the raw scores back to the original metric used in the scores used in the reference texts, as this allows us to compare the raw scores of the virgin texts with the assigned scores of the reference texts. In their original paper, Laver et al. suggest the following transformation:

$$S_{vd}^* = (S_{vd} - S_{\bar{v}d}) \left(\frac{SD_{rd}}{SD_{vd}} \right) + S_{\bar{v}d} \quad (4)$$

Here, S_{vd}^* is the transformed score, S_{vd} the raw score, $S_{\bar{v}d}$ the average raw score of the virgin texts, and SD_{rd} and SD_{vd} the standard deviations of the reference and virgin text scores respectively. This metric preserves the mean of the virgin text scores, but equals their variance to that of the reference text scores, thus allowing for comparison.

Lowe (2008) points out that the LBG transformation assumes that the raw virgin text scores have the correct mean, but the incorrect variance. However, due to the large amount of overlapping words, the virgin score mean is invariably close to the reference text mean—an effect called shrinkage. These overlapping words are often words as ‘the’ or ‘and’, and as they occur frequently in all documents, they get centrist scores. As such, the distances between the virgin texts are shrunken, and all texts bounce towards the middle of the scale. Laver et al. fix this by recouping the original variance, but falsely assume that the newly derived mean is correct. This is no problem when the variance and mean are expected to be the same for both reference and virgin texts. However, as Lowe (2008, 359–360) notes, increasing polarisation between parties, or joint movement to the sides of a set of parties, makes it hard, if impossible, to discern whether the mean of the virgin texts is centrist due to the reference scores or a shrinkage artifact.

Martin & Vanberg (2008, 95–97) agree with the above criticism and note several more shortcomings of the Laver et al. transformation method. First, as the transformation uses the standard deviation of the virgin text raw scores it depends on the set of virgin texts themselves. This makes the scores non-robust with regard to the virgin texts, and any difference in the set of reference texts automatically leads to a difference in the scores. This way, a researcher could obtain different positions in the virgin texts solely because of a different selection in the reference texts. Second, despite what Laver et

al. claim, their method fails to recover the accurate relative distance ratios and therefore put the transformed scores and the virgin scores on the same metric. This is due to shrinkage, as we pointed out above. To combat these problems, Martin & Vanberg (2008) provide a new transformation based on the idea of relative distance ratios S_i :

$$S_i = \frac{S_i - S_{R1}}{S_{R1} - S_{R2}} \quad (5)$$

where two ‘anchoring texts’ S_{R1} and S_{R2} are chosen, and the placement of all other texts are expressed in relation to this ‘standard unit’ (Martin & Vanberg 2008, 97). They then use these ratios to construct a new transformation:

$$S_{vd}^* = \left((S_{vd} - S_{R1}) \frac{A_{R2} - A_{R1}}{S_{R2} - S_{R1}} \right) + A_{R1} \quad (6)$$

Here, S_{vd}^* is the transformed score, S_{vd} the raw score, A_{R1} and A_{R2} are the assigned scores to reference texts $R1$ and $R2$ (where $R1$ is located to the left of $R2$), and S_{R1} and S_{R2} are the reference texts’ raw scores. In their article, Martin & Vanberg use two reference texts, or ‘anchor texts’ located to the left and right of virgin texts. As seen in equation (6) above, both the assigned scores for the reference texts are recovered, and the virgin texts are thus placed on the original metric. However, as soon as more than two reference texts are used—as Laver, Benoit & Garry (2003) strongly advise—not all the original exogenous scores of the reference texts can be recovered exactly, as only two texts can be used to define the metric. MV thus suggest a change to the transformation:

$$S_{vd}^* = \left((S_{vd} - S_{Rmin}) \frac{A_{Rmax} - A_{Rmin}}{S_{R2} - S_{R1}} \right) + A_{Rmin} \quad (7)$$

Here A_{Rmin} and A_{Rmax} denote the lowest and highest placed reference text on the original metric. The positions of these texts will be recovered exactly, while the scores of the other texts will be distorted as the relative distance ratios of the raw scores do not correspond to the relative distance ratios of the reference scores. Comparison between reference and virgin texts thus becomes difficult and researchers face a trade-off between increased accuracy of the dictionary and internal consistency, and the ability to make valid comparisons (Martin & Vanberg 2008) (see Appendix G).

To conclude, while the transformation by Laver, Benoit & Garry (2003) depends on the virgin texts and is indifferent to the composition of the reference texts, the transformation by Martin & Vanberg (2008) depends on the reference texts and is indifferent to the composition of the set of virgin texts (Lowe 2008, 360). Moreover, Laver et al. assume that the variances of both the set of reference texts and virgin texts are the same, while the Martin & Vanberg transformation does not do so (Benoit & Laver 2008, 110). In this paper, we use both transformation methods as we have no use for the raw scores and neither of the scores has until now proven to be the most appropriate in all circumstances.

More generally, Lowe (2008) criticized *Wordscores* for its heavy dependence on reference texts. Lowe (2008, 366–368) views *Wordscores* as an approximation to correspondence analysis and goes on to treat the method as a statistical ideal point model for words. In doing so, he identified six conditions that *Wordscores* needs to fulfill in order to ensure consistent and unbiased estimation of the parameters of the ideal point model:

1. The word scores of the virgin texts need to be equally spaced and extend over the whole range of word scores for the reference texts
2. The word scores of the virgin texts need to be spaced relative to the informativeness term (all texts are thus informative)
3. The reference scores of the reference texts need to be equally spaced and extend past each word score of the virgin texts in both directions
4. The word scores of the reference texts need to be spaced relative to the informativeness term (all texts are thus informative)
5. All the words need to be equally informative
6. The probability of seeing a word needs to be the same for all words

According to Lowe (2008, 369), conditions 5 and 6 will never hold for word count data because any text exhibits a highly skewed word frequency distribution, regardless of the genre, and contain many uninformative words. Nevertheless, we can significantly reduce these problems by filtering out uninformative words such as stop words, function words that do not convey meaning but primarily serve grammatical functions, very uncommon words, and words which appear in less than 1% and more than 99% of documents in the corpus (Grimmer & Stewart 2013). Doing this makes the probability of seeing a word more equal, and removes non-informative words.

Conditions 1 and 2 will be less likely to hold when there is not enough overlap between word distributions between the reference documents. However, by using many documents as reference texts (as Laver et al. advised), the conditions might be well approximated. Condition 2, however, suffers from the fact that some documents are small, and thus contain very little to no information. This does not only increase the confidence intervals around the estimates, but also creates a large bias in the estimates, negatively influence the validity of the virgin documents scores.

Conditions 3 and 4 are similar to 1 and 2, but as words are more plentiful than texts, the changes of insufficient overlap are considerably lower, and the conditions are thus less important. Lowe even states ‘we might hope that they [words] may relatively evenly spread out across a policy dimension’ (Lowe 2008, 369), which makes the conditions even more plausible. Last, Lowe (2008, 369) considers that conditions 1 and 3 can never hold simultaneously, as this would require an infinite data set—and thus concludes that bias in *Wordscores* is inevitable.

Apart from the differences in transformation, the software implementation of the *Wordscores* algorithm in Stata and R introduced three further changes in the way *Wordscores* estimation is implemented compared to the formulas and illustration in Laver et al.

The first concerns the definition of F_{wv} in equation 3 in Laver et al. According to Laver, Benoit & Garry (2003, 316), F_{wv} denotes ‘the relative frequency of each virgin text word [w], as a proportion of the total number of words in the virgin text [v]’ (emphasis added). Most of the software implementations of *Wordscores* however (including ‘v0.36’ in Stata and all the implementations in R, namely ‘austin’ and ‘quanteda’), define F_{wv} as the relative frequency of each virgin text word w is taken as a proportion of the total number of words co-occurring between the reference and the virgin texts. The only exception to this is the ‘23-June-2009’ implementation in Stata which follows the definition of Laver et al. As we show in the Appendix B, the two definitions lead to considerable differences in the results.

The second difference refers to the presence of a smoothing parameter. Smoothing works by adding a constant (e.g. 1) in the data frequency matrix to account for words that are being used only once in one document and never in other documents, on the presumption that such words may reflect choices in language usage that do not carry as much information as to the underlying quantity of interest. From quanteda 1.3 the smoothing parameter default is zero to match the description in Laver, Benoit & Garry (2003).

The third difference refers to whether the reference texts are included in the set of virgin texts that are used in estimation. While Laver, Benoit & Garry (2003) do not treat reference texts together with virgin texts and the

implementation of *Wordscores* in Stata made their inclusion optional, the implementations of *Wordscores* in R included reference texts in the estimation as a default. With *quanteda* 1.1.1 it became possible to exclude reference texts from estimation by using the “`include_reftexts`” argument, but from 1.3 it is only possible to exclude reference texts by specifying the “`newdata`” option accordingly.

Appendix B: Reanalysis of Laver, Benoit & Garry (2003)

Much of the initial validation for *Wordscores* rested on scoring the 1997 Irish manifestos on a social and economic dimension using the 1992 manifestos as reference texts (Laver, Benoit & Garry 2003). We attempted to replicate the findings in the paper using the manifestos, code, and reference scores as available on the *Wordscores* website http://www.tcd.ie/Political_Science/wordscores/index.html. Unfortunately, we were not able to replicate the results published in Laver et al. using the materials from the website. Upon closer examination we realized that replication is not possible for two reasons.

First, the reference texts provided in the *Wordscores* website are not the same as the ones used in the Laver et al. article. As is clear from the number of words, the documents provided in the website have been cleaned differently compared to the documents used in the Laver et al. article. This cleaning refers to the removal of numbers, special characters, document formatting content (tables of contents, headers, footers), and occasionally stop words which is an important step in computer-assisted text analysis. Moreover, the website, includes in the set of reference texts the manifestos of two additional parties (Greens and Sinn Fein), unlike the Laver et al. article which uses as reference texts the manifestos of only five parties.

Second, and most importantly, the current (as of December 16, 2019) ‘23-June-2009’ version of `wordscores` for Stata gives different results than the older version ‘v0.36’ that was used to produce the results in the Laver et al. article. The differences in the output given by these two versions can be attributed to changes in the code with regards to how F_{wv} (equation 3 in the main text) is calculated. According to Laver, Benoit & Garry (2003, 316), F_{wv} denotes ‘the relative frequency of each virgin text word [w], as a proportion of the total number of words in the virgin text [v]’ (emphasis added). This is what has been implemented in the ‘23-June-2009’ version of the Stata `wordscores` package. Conversely, ‘v0.36’ and the two packages that can implement *Wordscores* in R (‘austin’ and ‘quanteda’), define `Fwv` as the relative frequency of each virgin text word `w` is taken as a proportion of the total number of words co-occurring between the reference and the virgin texts. In an e-mail communication, Kenneth Benoit clarified that the ‘correct’ implementation of *Wordscores* is in the R packages and ‘v0.36’ version of `wordscores` for Stata. This implies that the definition of F_{wv} given in Laver et al. is incorrect. It also implies that all those who used the ‘23-June-2009’ version in their (published) papers got the ‘wrong’ *Wordscores* results. In our communication, Kenneth Benoit also indicated that the change in how

F_{wv} is defined does not make much difference as the results correlate highly.

Figure 1: Comparing the results of the two implementations of F_{wv} in `wordscores` for Stata.

We tested this claim by implementing the two versions of `wordscores` (v0.23 and ‘23-June-2009’) for Stata across all the parties in our analysis for four different dimensions (left-right, European integration, economic, social) using the Benoit & Laver (2006) expert survey for the reference text scores and the LBG transformation. Figure A1 shows the results which clearly contradict the claim that the results of the two implementations correlate would highly (‘about .97’). The concordance between the two scores measured by the concordance correlation coefficient are .44 (left-right), .53 (European integration), .33 (economic), .32 (social). The respective Pearson correlation coefficients are .55, .62, .41, .38. The correlations are similar when different sources for the reference text scores were used. This is clear evidence that changing the definition of F_{wv} changes the *Wordscores* estimates radically.

Nevertheless, the most important point here is that the inconsistency between the Laver et al. article and the software implementations challenges the proof-of-concept validation presented in the Laver et al. article. In the figures presented in Table 1 below, we show how the *Wordscores* estimates for Irish party positions vary when one uses different sets of documents for reference texts (five parties as in the Laver et al. article versus seven parties as in the replication material found in the *Wordscores* website) and different implementations of `wordscores` for Stata (‘v0.36’ versus ‘23-June-2009’) lead to substantially different results.

The results in the top left quartile of Table 1 attempt to replicate the findings of Laver et al. by using the manifestos of five Irish parties (FF, FG, Labour, DL, PD) and the ‘v0.36’ `wordscores` for Stata (which is identical to the `wordscores` and `quanteda` packages in R). They are almost identical

save some minor differences due to the way the documents were cleaned for the analysis in Laver et al. As pointed out in that article, the results look reasonable and consistent with how the parties have been placed in expert surveys (e.g. DL and Labour on the economic left, the other parties on the economic right).

However, when we change the definition of v from ‘the total number of words in the virgin text’ as stated in the original article Laver, Benoit & Garry (2003, 316) to ‘the proportion of the total number of words co-occurring in the virgin and reference texts’ as was done in the ‘23-Jun-2009’ version of `wordscores` for Stata, we get the much different results presented in the bottom left quartile. It is clear from the figure that changing the definition of v produces estimates that move parties in a way that does not make much sense (for instance, Fianna Fail as the most economically left party) and otherwise makes it impossible to distinguish between the parties given the confidence intervals of the estimates.

The change in the definition of v that was implemented on 23 June 2009 will produce party positions that appear reasonable and intuitive only if one adds the manifestos of Greens and Sinn Fein in the set of reference texts as shown in the bottom right quartile. However, if we add these two manifestos in the set of reference texts, but keep the definition of v as in the Laver et al. article, we will get the results in the top right quartile. Again, these results do not make much sense, since the confidence intervals overlap significantly and many of the point estimates are rather implausible (e.g. the Greens and Sinn Fein are in the middle of both scales).

We find it strange that the documents for Greens and Sinn Fein were not included in the APSR article, but were included in the replication of the article as implemented in the *Wordscores* website which contained a different Stata `wordscores` code. Why did the authors not include the SF and Greens documents in their original analysis as presented in the APSR article? We believe that this was not done because the addition of these two parties in 2003 under the alternative definition of v which is used in R and is favoured by Kenneth Benoit (as per our e-mail communication) would have given results that are inconsistent with expert surveys. Similarly, when the `wordscores` code was changed and the results appeared to be implausible, the two documents were added as reference texts in the replication materials in the *Wordscores* to improve the validity of the results. Since the positions of parties under the Laver et al. transformation (which is used in the APSR article) are sensitive to the inclusion/exclusion of virgin texts as shown by Martin & Vanberg (2008), we ask whether the exclusion of SF and the Greens from the analysis in Laver et al. but their inclusion in the ‘replication’ of the analysis in the *Wordscores* website does not constitute an attempt to ‘cherry

pick' among different possible results in a way that supports the argument in favour of *Wordscores*.

Appendix E: Content validity

According to Carmines & Zeller (1979), content validity refers to whether the method used for measuring a latent construct represents all of its facets. If one uses multiple indicators that are scaled in a single index, then these indicators should represent all facets of the construct. Alternatively, if one uses a single indicator (for instance as done in surveys asking for a left-right placement) then this indicator has to capture all different facets of the construct. Moreover, a measure that includes facets that do not belong to the construct would be problematic in terms of content validity. As noted in the section about the previous validation attempts, the evaluation of content validity is usually of qualitative nature, so it would be difficult to see how it could be assessed in the context of *Wordscores* output. We propose a workaround this problem by conceptualizing the construct in the context of *Wordscores* as being represented by the words used in the reference texts.

When *Wordscores* places virgin texts on a dimension of interest it does so by calculating a wordscore for each of the words occurring in the reference texts. As *Wordscores* is non-discriminating and scores all words on all dimensions, treating all words as equally informative of the dimension of interest is problematic in terms of content validity. This is because we should not expect each and every word in a reference text to be associated with a dimension of interest, no matter what this dimension is. This problem of *Wordscores* is known, of course, but here we are interested in quantifying the degree of content validity in order to investigate how big of a problem it is for estimating parties' positions.

To do so, we decided to treat each of the words scored in the reference texts as an indicator of the latent concept, and evaluated whether these words relate to the latent concept/dimension of interest. To assess this, following Krippendorff (2004, 101–102) we looked at the context in which these word appear. For example, the word 'committee' can be indicative of a party's position in the dimension of EU integration when it refers to an EU committee, but not when it refers to other types of committees. We therefore hand-coded *each and every word* in the reference texts to see how many of the words used to score the virgin texts were actually used in the context of the dimension of interest. As this is a particularly time-consuming process, we restricted this analysis to British documents and the European integration dimension. Our choice of British parties should be fair for *Wordscores* given that British Euromanifestos are some of the best documents in terms of relevance for assessing parties' positions on European integration. For our hand-coding exercise we defined the context as a natural sentence that starts with a capital letter, and end with one of the following delimiters: '.', '?', '!', ';', (Däubler, Benoit, Mikhaylov & Laver 2012, 942). Items in (bullet-pointed) lists were considered as separate sentences. Each word was coded as one (1) when it was used in a context referring to European integration and zero (0) otherwise.

In Figure 2 we plotted the distribution of the average hand-coding evaluation for among all the words used in each virgin document of each British party. What

Figure 2: Assessing content validity against hand-coding in the European integration dimension (I).

Note: The horizontal axis refers to the rate in which words were considered by the hand-coding to be relevant.

Figure 3: Assessing content validity against hand-coding in the European integration dimension (II).

Note: The horizontal axis refers to the rate in which words were considered by the hand-coding to be relevant.

is clear from the figure is that the vast majority of words used by *Wordscores* to estimate party positions are not particularly informative if one looks at the context in which they appear. It appears that *Wordscores* uses far more noise than signal to estimate party positions. A similar pattern is shown in Figure 3 which plots the (hand-coded) word relevance against the wordscore across all British party Euromanifestos. The scatterplot shows no relationship between the two, indicating that wordscores are not particularly strong in terms of content validity.

If one considers that the noise brought by the non-informative words moves party positions towards the middle of the scale, one can understand the logic behind the LBG transformation which stretches the party scores towards the end points of the scale. Although we agree that one needs to make some kind of transformation

to account for the presence of noise that leads to the centrist bias in party positions, we do not agree that such a fundamental problem in content validity present in *Wordscores* can be solved by a simple transformation of the raw scores. To give an example, we examine closely the wordscoring of the 2009 UKIP manifesto. UKIP is well-known for its extreme anti-EU stance which should leave no doubts about where the party should be placed. The *Wordscores* raw placement for UKIP is 11.5 [11.2, 11.8] and the LBG transformed one is 9.3 [5.5, 13]. In either case, the party is placed in the middle of the scale. The transformation only improves this placement by specifying that this counter-intuitive middle placement is estimated with a lot of uncertainty. *Wordscores* tells us that UKIP could be placed on either side of the scale even though one should not have much difficulty in establishing the position of the party simply by looking at the UKIP Euromanifesto.

One could argue of course, that this is a problem of the 2009 UKIP Euromanifesto being very short. However, the size of the document should only contribute to making the confidence interval around the point estimate larger. However, the problem here is that the UKIP point estimate is counter-intuitively estimated in the middle of the scale. This is not because the UKIP document is short, but because *Wordscores* is unable to accurately estimate the party position due the noise that was introduced by the scoring of non-informative words. This is clearly shown in Figure 4, where we plotted all the words scored in the UKIP 2009 Euromanifesto according to their wordscore. Most of the words scored by *Wordscores* are not informative with regards to placing UKIP on the European integration dimension and since most of the words have wordscores near the middle of the scale, the point estimate for UKIP was counter-intuitively given at 11.5 on a 20-point scale (transformed by LBG to 9.3).

The problem is therefore deeper than the uncertainty that comes with the size of the documents, and this can be established simply by looking at the cases of parties with much larger documents than UKIP. The fundamental problem lies in the content validity of *Wordscores*. The lack of content validity brought by scoring each and every word irrespective of its relevance in providing information about the dimension of interest, pushes scores towards the middle of the scale. Transforming the raw scores will pull the estimates towards the endpoints of the scale, but there is no guarantee that the estimates will be pulled to the right direction.

Figure 4: Wordscoring the UKIP 2009 Euromanifesto on the European integration dimension.

Note: Word size corresponds to the frequency of appearance in the UKIP virgin text; words that were hand-coded as being relevant at least 50% of the instances are plotted in black.

Appendix F: Document parsing

Following an approach similar to Proksch & Slapin (2006), we report an example where documents were parsed into different policy areas before estimation. The particular example regards five British parties' Euromanifestos which we manually parsed each of them into two different documents: a document containing the sections referring to economic policies, and a document containing the sections referring to social policies. Figure 5 compares the *Wordscores* estimates for the parsed versus unparsed documents against the 2010 CHES, according to the LBG transformation, while Figure 6 does the same for the MV transformation. In all cases reference scores were taken from the 2006 CHES. As evident from Figure 5, while the *Wordscores* estimates for the parsed and unparsed documents are statistically indistinguishable in socio-economic dimension, some of the parsed document estimates in the socio-cultural dimension are closer to the CHES estimates compared to the unparsed document estimates (Labour, SNP, PC), one is further away (Conservatives), and in one case there is no difference between the two (Liberal Democrats). The picture in the socio-cultural dimension is largely similar when one considers the MV transformation, but the picture is more inconclusive when one looks at the socio-economic dimension where using the parsed documents reveals some improvement in the estimates for the Conservative Party estimate and a worsening for the Labour Party estimate.

While the example using British party Euromanifestos provides some, rather limited, evidence in favour of using parsed documents for estimation with *Wordscores*, we refrain from extending the analysis to all countries in our main analysis for two reasons. Firstly, parsing documents into two different policy areas is time-consuming process (as some Euromanifestos are several dozen pages long) and requires extensive skills in many European languages. Investing so much time and so many resources would make an unfair test for a method that promised to be 'simple', 'quick', 'easy', 'effortless', and 'language blind' (Laver, Benoit & Garry 2003, 312, 317, 323–326, 328). Secondly, parsing manifestos into different policy area can, by large, involve a lot of subjective choices, as it has been shown for the Manifestos Project (Däubler et al. 2012, Mikhaylov et al. 2012). We leave it to researchers to decide whether parsing documents before estimation is worth the effort when it comes to using *Wordscores*.

Figure 5: Parsed versus unparsed documents estimates on the socio-economic and socio-cultural dimensions (LBG transformation).

Note: Triangles indicate *Wordscores* estimates based on unparsed documents, squares indicate *Wordscores* estimates based on parsed documents, and dots indicate the 2006 CHES estimates.

Figure 6: Parsed versus unparsed documents estimates on the socio-economic and socio-cultural dimensions (MV transformation).

Note: Triangles indicate *Wordscores* estimates based on unparsed documents, squares indicate *Wordscores* estimates based on parsed documents, and dots indicate the 2006 CHES estimates.
